

Bottom up parses:Introduction:

→ bottom-up parse corresponds to the construction of a parse tree for an input string beginning at the leaves (the bottom) and working up towards the root (the top)

→ e.g: A bottom-up parse for  $id * id$

Handle pruning:

Bottom up parsing during a left-to-right scan of the input constructs a right-most derivation in reverse. Informally a 'handle' is a substring that matches the body of the production, and whose reduction represents one step along the reverse of the right-most derivation

Example:

adding subscripts to the tokens  $id$  for clarity, the handles during the parse of  $id_1 * id_2$  alc to the expressions

grammar  $\rightarrow \left\{ \begin{array}{l} E \rightarrow E + T / T \\ T \rightarrow T * F / F \\ F \rightarrow (E) / id \end{array} \right\}$  are shown in the figure.

Although  $T$  is the body of the production  $E \rightarrow T$ , the symbol  $T$  is not a handle in the sentential form  $T * id_2$ . If  $T$  were indeed replaced by  $E$ , we would get a string  $E * id_2$ , which cannot be derived from the start symbol  $E$ . Thus, the leftmost substring that matches the body of some production need not be a handle.

formally, if  $S \xrightarrow{nm} \alpha Aw \xrightarrow{nm} \alpha \beta w$

RIGHT SENTENTIAL FORM	HANDLE	REDUCTION PRODUCTION
$id_1 * id_2$	$id_1$	$F \rightarrow id$
$f * id_2$	$F$	$T \rightarrow F$
$T * id_2$	$id_2$	$F \rightarrow id$
$F$	$T * F$	$E \rightarrow T * F$

Handles during a parse of  $id_1 * id_2$  (a)

Formally, if  $S \xrightarrow{nm} \alpha Aw \xrightarrow{nm} \alpha \beta w$ , as in figure (b), then production  $A \rightarrow \beta$ , in the position following  $\alpha$  is a handle of  $\alpha \beta w$ . Alternatively, a handle of a right sentential form  $\gamma$  is a production  $A \rightarrow \beta$  and a position of  $\gamma$  where the string  $\beta$  may be found, such that replacing  $\beta$  at that position by  $A$  produces the previous right sentential form in a rightmost derivation of  $\gamma$ .

Note that the string  $w$  to the right of the handle must contain only terminal symbols. For convenience, we prefer to the body  $\beta$  rather than  $A \rightarrow \beta$  as a handle. Note we "a handle" rather than "the handle", because

The grammar could be ambiguous, with more than one rightmost derivation of  $\alpha\beta\omega$ . If a grammar is unambiguous, then every right-sentential form of the grammar has exactly one handle.

A right-most derivation in reverse can be obtained by "handle pruning". That is, we start with a string of terminals  $w$  to be parsed. If  $w$  is a sentence of a grammar at hand, then let  $w = T_n$ , where  $T_n$  is the  $n^{\text{th}}$  right sentential form of some as yet unknown rightmost derivation.

$$S = T_0 \xrightarrow{\text{rm}} T_1 \xrightarrow{\text{rm}} T_2 \xrightarrow{\text{rm}} \dots \xrightarrow{\text{rm}} T_{n-1} \xrightarrow{\text{rm}} T_n = w$$

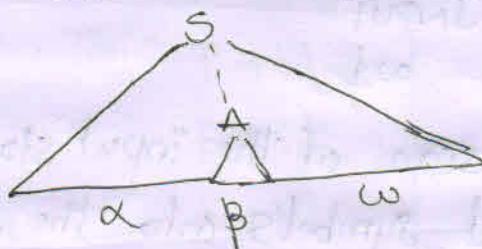

Figure (b). A handle  $A \rightarrow B$  in the parse tree for  $\alpha\beta\omega$ . To reconstruct this derivation in reverse order, we locate the handle  $B_n$  in  $T_n$  and replace  $B_n$  by the head of relevant production  $A_n \rightarrow B_n$  to obtain the previous right sentential form  $T_{n-1}$ . Note that we do not know how handles are to be found, but we shall see methods of doing so shortly.

We then repeat this process. That is we locate the handle  $B_{n-1}$  in  $T_{n-1}$  and reduce this handle to obtain the right sentential form  $T_{n-2}$ . If by continuing this process we produce a right sentential form consisting only of the start symbol  $S$ , then we halt & that's successful.

## Shift-Reduce parsing:

Shift-reduce parsing is a form of bottom up parsing in which a stack holds grammar symbols and an input buffer holds the rest of the string to be parsed.

→ we use \$ to mark the bottom of the stack and also the right end of the input. Conventionally, when discussing bottom-up parsing, we show the top of the stack on the right, rather on the left as we did for top-down parsing.

Initially, the stack is empty, and string  $\omega$  is on the input, as follows:

STACK	INPUT
\$	$\omega\$$

During left to right scan of the input string, the parser shifts zero/more input symbols onto the stack until it is ready to reduce a string  $\beta$  of the grammar symbols on top of the stack. It then reduces  $\beta$  to the head of the appropriate production. The parser repeats this cycle until it has reduced an entire  $\omega$  until the stack contains the start symbol and input is empty.

## Actions in shift-reduce parsing:

1. Shift: shift the next input symbol onto the top of stack
2. Reduce: The right end of the string to be reduced must be at the top of the stack. Locate the left end of the string within the stack and decide with what non-terminal to replace the string

3. Accept: Announce successful completion of parsing  
 4. Error: Discover a syntax error and can an error recovery routine

Find the handles for the given RSF and construct shift-reduce parser:

$$\begin{aligned} E &\rightarrow E+T|T \\ T &\rightarrow T*F|F \\ F &\rightarrow (E)|id \end{aligned}$$

illp: id + id

## Types of conflicts in shift-reduce parsers

### Conflicts during shifts - Reduce parsing:

There are CNFG's for which shift-reduce parsing cannot be used. Every shift-reduce parser for such a grammar can reach a configuration in which the parser, knowing the entire stack contents & the next input symbol

#### Types:

##### i) shift/reduce conflict:

→ Cannot decide whether to shift or to reduce  
called Shift-reduce Conflict

##### ii) reduce/reduce conflict:

→ Cannot decide which of several reductions to make called Reduce-reduce Conflicts

eg: Consider the grammar

$$E \rightarrow E+E$$

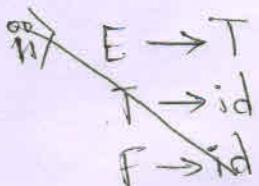

$$\quad | \quad E-E$$

$$\quad | \quad \text{NUM}$$

$$\quad | \quad \text{ID}$$

inp: 2+3\*4

No.	Stack	operation/grammar
1	2 NUM	shift 2
2	E	reduce $E \rightarrow \text{NUM}$
3	E+	shift +
4	E+3	shift 3
5	E+E	reduce $E \rightarrow \text{NUM}$
6	E	reduce $E \rightarrow E+E$ on shift *
		ie Shift-reduce Conflict

id+.

21/12/22

Bi) Bi ...

eg 2) An ambiguous grammar can never be LR. For e.g., consider the dangling-else grammar

$\text{stmt} \rightarrow \text{if expr then stmt}$   
 $| \quad \quad \quad \text{if expr then stmt else stmt}$   
 $| \quad \quad \quad \text{other}$

If we have a shift-reduce parser in configuration like this

STACK	INPUT
... if expr then stmt	else ... \$

→ we cannot tell whether if expr then stmt is the handle, no matter what happens below it on the stack. here there is a shift/reduce conflict. Depending on what follows the else on the input, it might be correct to reduce if expr then stmt to stmt, or it might be correct to shift else then to look for another stmt to complete the alternative if expr then stmt else stmt

- eg 3) (1)  $\text{stmt} \rightarrow id (\text{parameter\_list})$   
(2)  $\text{stmt} \rightarrow \text{expr} := \text{expr}$   
(3)  $\text{parameter\_list} \rightarrow \text{parameter\_list}, \text{parameter}$   
(4)  $\text{parameter\_list} \rightarrow \text{parameter}$   
(5)  $\text{parameter} \rightarrow id$   
(6)  $\text{expr} \rightarrow id (\text{expr\_list})$   
(7)  $\text{expr} \rightarrow id$   
(8)  $\text{expr\_list} \rightarrow \text{expr\_list}, \text{expr}$   
(9)  $\text{expr\_list} \rightarrow \text{expr}$

STACK  
.. id (id

INPUT  
, id) ...

In the problem id on the top of the stack must be reduced, but by which production? The correct choice is production(5) if p is a procedure, but production(7) if p is an array. The stack does not tell which; information in the symbol table obtained from the declaration of p must be used.

So, In this case we have the conflict that reduce id by parameter or expr. It is called as Grede-reduce Conflict.

↳ conflict between reduce & reduce  
↳ conflict between reduce & non-terminal  
↳ conflict between non-terminal & non-terminal

equi -> equi -> bi (2)

rlowering & bi -rlowering & bi -rlowering (3)

rlowering -> bi -rlowering (4)

bi -rlowering (5)

(right-rlowering) bi -> rqls (6)

bi -rqls (7)

rqls, left-rlowering & bi -rlowering (8)

rqls -> bi -rlowering (9)

SLR parser: | SLR(1) | LR(0)

↳ Lookahead symbol

→ read in reverse

→ Scan from left to right

→ Simple

1. No left recursion and left factoring
2. Augment the grammar
3. Number the productions
4. Find the closure of item set (LR(0) item) & goto function
5. find first and follow set
6. Construct the SLR parsing table
  - shift reduce
  - reduce reduce
7. parse the input string

### Closure of Item Sets

If  $I$  is a set of items for a grammar  $G$ , then  
 $\text{CLOSURE}(I)$  is the set of items constructed from  $I$   
by the two rules

1. Initially, add every item in  $I$  to  $\text{CLOSURE}(I)$ .
2. If  $A \rightarrow \alpha \cdot B\beta$  is in  $\text{CLOSURE}(I)$  and  $B \rightarrow \gamma$  is a production, then add the item  $B \rightarrow \cdot \gamma$  to  $\text{CLOSURE}(I)$ .  
If it is not already there, apply this rule until no more new items can be added to  $\text{CLOSURE}(I)$ .

## Algorithm for Computation of CLOSURE

SetOfItems CLOSURE(I) {

A convenient way to implement the function closure is to keep a boolean array added, indexed by the nonterminals of  $G_1$ , such that  $\text{added}[B]$  is set to true if and when we add the item  $B \rightarrow \cdot \gamma^*$  for each  $B$ -production  $B \rightarrow \gamma$ .

SetOfItems CLOSURE(I)

$J = I;$

repeat

for (each item  $A \rightarrow \alpha \cdot B \beta$  in  $J$ )

for (each production  $B \rightarrow \gamma$  of  $G$ )

if ( $B \rightarrow \cdot \gamma$  is not in  $J$ )

add  $B \rightarrow \cdot \gamma$  to  $J$ ;

until no more items are added to  $J$  on one round;

return  $J$ ;

Note that if one  $B$ -production is added to the closure of  $I$  with the dot at the left end, then all  $B$ -productions will be similarly added to the closure. Hence, it is not necessary in some circumstances actually to list the items  $B \rightarrow \cdot \gamma$  added to  $I$  by CLOSURE. A list of nonterminals  $B$  whose productions were so added will suffice.

We divide all the sets of items of interest into two classes:

### 1. Kernel items:

The initial item,  $S' \rightarrow .S$ , all items whose dots are not at the left end.

### 2. Non-kernel items:

all items with their dots at the left end, except for  $S' \rightarrow .S$ .

### The Function GOTO :

The GOTO( $I, X$ ) function, where  $I$  is a set of items and  $X$  is a grammar symbol. GOTO( $I, x$ ) is defined to be the closure of the set of all items  $[A \rightarrow \alpha X \beta]$  such that  $[A \rightarrow \alpha X \beta]$  is in  $I$ . Intuitively, the GOTO function is used to define the transitions in the LR(0) automaton for a grammar. The states of the automaton corresponds to set of items, and GOTO( $I, x$ ) specifies the transition from the state for  $I$  under input  $x$ .

### Algorithm for Computation of LR(0) items :

```
Void items( $G'$ ) {
```

```
    C = CLOSURE({ $[S' \rightarrow .S]$ });
```

```
    repeat
```

```
        for(each set of items I in C)
```

```
            for(each grammar symbol X)
```

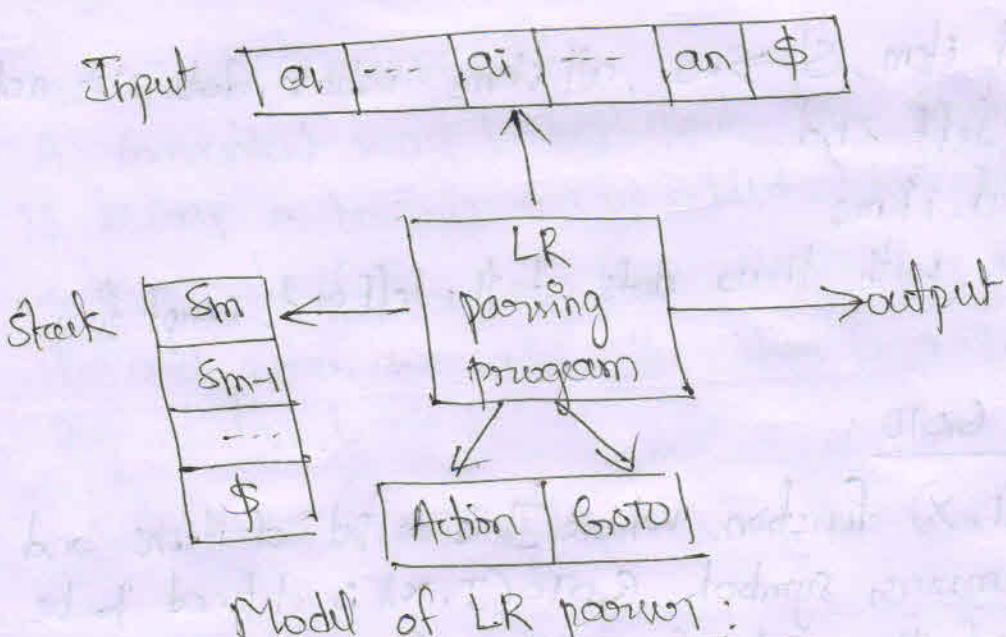

```
                if(GOTO(I, x) is not empty and not in C)
```

```
                    add GOTO(I, x) to C;
```

```
        until no new set of items are added to C.
```

```
    } on a stand;
```

## The LR-Parsing Algorithm

A schematic of an LR parser is shown in figure. It consists of an input, an output, a stack, a driver program. The driver program is the same for all LR parsers; only the parsing table changes from one parser to another. The parsing program reads characters from an input buffer one at a time, where a shift-reduce parser would shift a symbol, an LR parser shifts a table state. Each state summarizes the information contained in the stack below it.

### Structure of the LR parsing table:

The parsing table consists of two parts: a parsing-action function ACTION and a goto function GOTO.

1. The ACTION function takes as arguments a state  $i$  and a terminal  $a$  (or  $\$$ , the input endmarker). The value of  $ACTION[i, a]$  can have one of four forms:

- b) If  $[A \rightarrow \alpha \cdot]$  is in  $I_i$ , then set  $\text{ACTION}[i, \alpha]$  to "reduce  $A \rightarrow \alpha$ " for all  $\alpha$  in  $\text{Follow}(A)$ ; here  $A$  may not be  $S$ .
- c) If  $[S \rightarrow S \cdot]$  is in  $I_i$ , then set  $\text{ACTION}[i, \$]$  to "accept."

If any conflicting actions results from the above rules, we say the grammar is not SLR(1). The algorithm fails to produce in this case.

3. The goto transitions for state  $i$  are constructed for all nonterminals  $A$  using the rule:

$$\text{If } \text{GOTO}(I_i, A) = I_j \text{ then } \text{GOTO}[i, A] = j$$

4. All entries not defined by rules (2) and (3) are made "error".

5. Initial state of the parser is the one constructed from the set of items containing  $[S \rightarrow \cdot S]$ .

- (a) shift  $j$ , where  $j$  is a state. The action taken by the parser effectively shifts input  $a$  to the stack, but uses state  $j$  to represent  $a$ .
- (b) Reduces  $A \rightarrow \beta$ . The action of the parser effectively reduces  $\beta$  on the top of the stack to head  $A$ .
- (c) Accept. The parser accepts the input and finishes parsing.
- (d) Error. The parser discovers an error in its input and takes some corrective action. We shall have more to.

2. We extend the GOTO function, defined on sets of items, to states: if  $\text{GOTO}[I_i, A] = I_j$ , then GOTO also maps a state  $i$  and a nonterminal  $A$  to state  $j$ .

### Algorithm for LR parsing:

INPUT: An input string  $w$  and an LR-parsing table with functions ACTION and GOTO for a grammar  $G$ .

OUTPUT: If  $w$  is in  $L(G)$ , the reduction steps of a bottom-up parse for  $w$ ; otherwise, an error production indication.

METHOD: Initially, the parser has  $S_0$  on its stack, where  $S_0$  is the initial state, and  $w\$$  in the input buffer.

Let  $a$  be the first symbol of  $w\$$ ;

while(1) { /\* repeat forever \*/

    let  $s$  be the state on top of the stack;

    if (ACTION [ $s, a$ ] = shift  $t$ ) {

        push  $t$  onto the stack;

        let  $a$  be the next input symbol;

    } else if (ACTION [ $s, a$ ] = reduce  $A \rightarrow \beta$ )

4. pop[ $\beta$ ] symbols off the stack;  
 output the production  $A \rightarrow \beta$ ;  
 } else if ( $\text{ACTION}[S, a] = \text{accept}$ ) break; /\* parsing is done \*/  
 else call error-recovery routine.  
 }

### Constructing the SLR-parsing tables:

The SLR method for constructing parsing tables is a good starting point for studying LR parsing. We shall refer to the parsing table constructed by this method as an SLR table, and to an LR parser using an SLR-parsing table as an SLR parser. The other two methods augment the SLR method with lookahead information.

### Algorithm for constructing an SLR parsing table:

INPUT: An Augmented grammar  $G'$ .

OUTPUT: The SLR-parsing table functions ACTION and GOTO for  $G'$ .

#### METHOD:

1. Construct  $C = \{J_0, J_1, \dots, J_n\}$ , the collection of sets of  $LR(0)$  items for  $G'$ .
2. state  $i$  is constructed from  $J_i$ . The parsing actions for state  $i$  are determined as follows:
  - (a) If  $[A \rightarrow \alpha \cdot a \beta]$  is in  $J_i$  and  $GOTO(J_i, a) = J_j$ , then set  $\text{ACTION}[i, a]$  to "shift  $j$ ." There a must be a terminal.

- ⇒ If  $[A \rightarrow \alpha]$  is in  $I_i$ , then set  $\text{ACTION}[i, \alpha]$  to "reduce  $A \rightarrow \alpha$ " for all  $\alpha$  in  $\text{Follow}(A)$ ; here  $A$  may not be  $S'$ .
- ⇒ If  $[S \rightarrow S]$  is in  $I_i$ , then set  $\text{ACTION}[i, S]$  to "accept."

If any conflicting actions results from the above rules, we say the grammar is not SLR(1). The algorithm fails to produce in this case.

3. The goto transitions for state  $i$  are constructed for all nonterminals  $A$  using the rule:

$$\text{if } \text{Goto}(I_i, A) = I_j, \text{ then } \text{Goto}[i, A] = j$$

4. All entries not defined by rules (2) and (3) are made "error".

5. Total state of the parser is the one constructed from the set of items containing  $[S^* \rightarrow \cdot S]$ .

Viable prefix

The ~~prefix~~ of the RSF that can appear on the stack of shift reduce parser are called viable prefix. In other words the ~~viable prefix~~ is a prefix of a RSF that does not continue past the right end of the right most handle of that sentential form. By this, it is always possible to add terminal

### Viable prefix:

- The prefix on the Right Sentential form That can be appear on the stacks of S-R pairs are called Viable prefixes. In other words the Viable prefix Is a prefix Is a prefix of Right sentential form That does not continue past the right end of the rightmost handle of that sentential form by this It is always possible to add terminal symbols to the end of the Viable prefix to obtain the Right sentential form
- The Viable prefix Is based on the fact that LR(0) automata recognizes Viable prefixes

→ we say item  $A \rightarrow \beta_1, \beta_2$  is valid for a Viable prefix  $\alpha\beta_1$  if there is a derivation of the form  $S \xrightarrow[nm]{*} \alpha Aw \xrightarrow[nm]{*} \alpha\beta_1\beta_2 w$

→ In general, an item will be valid for many Viable prefixes

here  $A \rightarrow \beta_1, \beta_2$  tells us whether to shift/reduce when we find  $\alpha\beta_1$  on the parsing stack. In particular if  $\beta_2 \neq \epsilon$ , then we have to shift onto the stack if  $\beta_2 = \epsilon$ , then  $A \rightarrow \beta_1$  is the handle and we have to reduce by the production

eg:  $E \xrightarrow[nm]{*} F * id \xrightarrow[nm]{*} (E) * id$

at various times, during parse the stack will hold (, (E, (E) which are the viable prefix. but it should not hold (E)\* because, (E) is a handle, which the parser must reduce to F, before shifting \*

thus all the handles which will prevent having tokens in the stack

stack and parser stack  
stack of handles which have been reduced to tokens  
stack of handles which have been reduced to tokens, so that what is  
reduced from stack is added to parser stack  
that is number-taking, letter-taking, etc.
